Abstract

This paper investigates the link between the optimal level of non-financial firms' liquid assets and uncertainty. We develop a partial equilibrium model of precautionary demand for liquid assets showing that firms alter their liquidity ratio in response to changes in either macroeconomic or idiosyncratic uncertainty. We test this hypothesis using a panel of non-financial US firms drawn from the COMPUSTAT quarterly database covering the period 1993–2002. The results indicate that firms increase their liquidity ratios when macroeconomic uncertainty or idiosyncratic uncertainty increases.

of cash and cash equivalents and other liquid assets, as well as credit lines with banks, Honda believes that it maintains a sufficient level of liquidity.”¹

“Standard & Poor’s said those reserves have declined severely over the last year and blamed the drain, in part, on Schrempp’s massive spending spree, which included taking a 34 percent stake in debt-ridden Japanese automaker Mitsubishi Motors. According to an article in *Newsweek* magazine, DaimlerChrysler’s cash reserves — a cushion against any economic turndown — will dwindle to \$2 billion by the end of the year, down 78 percent from two years ago. That compares with cash reserves of more than \$13 billion at rivals General Motors and Ford, the magazine said.”²

Why should a company maintain considerable amounts of cash, as in Honda’s case? Why is a decline in cash reserves problematic as in DaimlerChrysler’s case? What determines the optimal level of non-financial firms’ liquidity? In the seminal paper of Modigliani and Miller (1958) cash is considered as a zero net present value investment. There are no benefits from holding cash in a world of perfect capital markets lacking information asymmetries, transaction costs or taxes. Firms undertake all positive NPV projects regardless of their level of liquidity.³

However, due to the presence of market frictions, we generally observe considerable variation in liquidity ratios among different types of firms according to their size, industry and degree of financial leverage. For instance, several studies suggest that for liquidity constrained firms, liquid asset holdings are positively correlated with proxies for the severity of agency problems. Myers and Majluf (1984) argue that firms facing information asymmetry-induced financial constraints are likely to accumulate cash holdings. Kim et al. (1998) indicate that firms increase investment in liquid assets in response to increase in the cost of external financing, the variance of future cash flows or the return on future investment opportunities.⁴ Harford (1999) argues that corporations with excessive cash holdings are less likely to be takeover targets. Almeida et al. (2004) develop a liquidity demand model where firms have access to investment opportunities but cannot finance them. They show that financially constrained firms’ cash-flow sensitivity increases during recessions, while financially unconstrained firms’ cash-flow sensitivity is unaffected by the business cycle.⁵

We aim to contribute to the literature on corporate liquidity by considering an additional factor which may have important effects on firms’ cash management behavior: the uncertainty they face in terms of both macroeconomic conditions and idiosyncratic risks. In explaining the role of macroeconomic uncertainty on cash-holding behavior, Baum et al. (2006) develop a static model of cash management under uncertainty with a signal extraction mechanism. In their empirical investigation, they find that firms behave more homogeneously in response to increases in macroeconomic uncertainty.⁶ However, their model implies predictable variations in the *cross-sectional distribution* of corporate cash holdings and does not make predictions about the individual firm’s optimal *level* of liquidity. Furthermore, they do not consider the impact of idiosyncratic uncertainty on the firm’s cash holdings.

In this paper, we complement Baum et al. (2006) by investigating the impact of macroeconomic uncertainty as well as idiosyncratic uncertainty on the cash-holding behavior of non-financial firms. We provide a theoretical and empirical investigation of the firm’s decision to hold liquid assets. Our theoretical model formalizes the individual firm’s precautionary demand for cash and assumes that the firm maximizes its value by investing in capital goods and holding cash to offset an adverse cash-flow shock. The optimal level of cash holdings is derived as a function of expected return on investment, the expected interest rate on loans, the finite bounds of their cash-flow distribution, the probability of getting a loan and their initial resources. We then parameterize optimal cash holdings and turn to the data to see if there is empirical support for the predictions of the model that managers change levels of liquidity in response to changes in both macroeconomic and idiosyncratic uncertainty. To do that, we match firm-specific data with information on the state of the macroeconomic environment.

To test the model’s predictions, we apply the System GMM estimator (Blundell and Bond, 1998) to a panel of US non-financial firms obtained from the quarterly COMPUSTAT database over the 1993–2002 period. After screening

⁶ In a recent paper, Bo and Lensink (2005) suggests that presence of uncertainty factors changes the structural parameters of the Q-model of investment.

procedures our data include more than 30,000 manufacturing firm-quarter observations, with 700 firms per quarter. Since the impact of uncertainty may differ across categories of firms, we also consider four sample splits. Our main findings can be summarized as follows. We find strong evidence of a positive association between the optimal level of liquidity and macroeconomic uncertainty as proxied by the conditional variances of inflation and the index of leading indicators. US companies also increase their liquidity ratios when idiosyncratic uncertainty increases. Results obtained from sample splits confirm findings from earlier research that firm-specific characteristics are important determinants of cash-holding policy.⁷

The remainder of the paper is organized as follows. Section 2 discusses the theoretical model of non-financial firms' precautionary demand for liquid assets. Section 3 describes our data and empirical results. Finally, Section 4 concludes.

2. Theoretical model

2.1. Model setup

We develop a two period cash buffer-stock model which describes how the firm's manager should vary the optimal level of liquid assets in response to macroeconomic and/or idiosyncratic uncertainty. We assume that the manager maximizes the expected value of the firm.

At time t the firm has initial resources W_{t-1} to be distributed between capital investment (I_t) and cash holdings (C_t). Cash holdings may include not only cash itself but also low-yield highly liquid assets such as Treasury bills. For simplicity, the firm does not finance any other activities. Investment is expected to earn a gross return in time $t+1$, denoted $E[R]_{t+1}$.⁸ Liquid asset holdings, C_t , are required to guard against a negative cash-flow shock.⁹ Prior to period $t+1$ the firm faces a random cash-flow shock ψ_t , distributed according to a symmetric triangular distribution with mean zero where $\psi_t \in [-H_t, H_t]$.¹⁰ Here H_t can be interpreted as a measure of uncertainty faced by the firm's managers.

There are three possible cases to consider, distinguished by a second subscript on each variable. They are graphically depicted in Appendix B. First, the firm can experience a positive cash-flow shock that occurs with probability p_1 and has conditional expectation $\psi_{t,1}$. This corresponds to the right half of the figure.

$$p_1 = \Pr(\psi_t > 0) = 1/2$$

$$\psi_{t,1} = E(\psi_t | \psi_t > 0) = H_t \left(1 - \frac{\sqrt{2}}{2}\right).$$

The firm's value in this case is

$$W_{t+1,1} = I_t E[R]_{t+1} + C_t + \psi_{t,1} = I_t E[R]_{t+1} + C_t + H_t \left(1 - \frac{\sqrt{2}}{2}\right). \quad (1)$$

Second, the firm could be exposed to a negative cash-flow shock yet may have enough liquid assets to meet it. In the figure, this corresponds to a cash-flow shock between $-C$ and 0. This shock occurs with probability p_2 and has conditional expectation $\psi_{t,2}$:

$$p_2 = \Pr(0 > \psi_t > -C_t) = \frac{1}{2} \frac{C_t(2H_t - C_t)}{H_t^2}$$

$$\psi_{t,2} = E(\psi_t | 0 > \psi_t > -C_t) = -C_t \left(1 - \frac{\sqrt{2}}{2}\right).$$

The value of the firm in the case when $-C_t < \psi_t < 0$ is equal to

$$W_{t+1,2} = I_t E[R]_{t+1} + C_t + \psi_{t,2} = I_t E[R]_{t+1} + C_t \frac{\sqrt{2}}{2}. \quad (2)$$

Finally, the size of the negative shock could exceed the available liquid assets of the firm.

⁷ For instance, see Ozkan and Ozkan (2004) and the references therein.

⁸ For simplicity we assume that distribution of returns is independent from all other variables' distributions.

⁹ The model ignores the transaction motive for holding cash, and the optimal amount of liquid assets is zero in the absence of costly external financing.

¹⁰ The triangular distribution is chosen as an approximation to the normal distribution, which does not have a closed-form solution.

This event occurs with probability p_3 and has conditional expectation $\psi_{t,3}$:

$$p_3 = \Pr(-C_t > \psi_t) = \frac{H_t^2 - 2H_t C_t + C_t^2}{2H_t^2}$$

$$\psi_{t,3} = E(\psi_t | -C_t > \psi_t) = -H_t + \frac{\sqrt{2}}{2}(H_t - C_t).$$

In this case the firm must seek external finance and borrow $-(\psi_t + C_t)$ at the gross rate X_t . However, there is a probability $s_t \in [0, 1]$ that the firm will be extended sufficient credit to prevent negative net worth. This implies that with probability $(1 - s_t)$ the firm declares bankruptcy and its value at time $t + 1$ is zero.¹¹ In the figure, this corresponds to a cash-flow shock between $-H$ and $-C$. For simplicity we assume that the probability of being granted sufficient credit is independent of the distribution of cash-flow shocks. The value of the firm in the last case is equal to

$$W_{t+1,3} = s_t(I_t E[R]_{t+1} + C_t + \psi_{t,3} + X_t(\psi_{t,3} + C_t))$$

$$= s_t \left[I_t E[R]_{t+1} - (1 + X_t)(H_t - C_t) \left(1 - \frac{\sqrt{2}}{2} \right) \right]. \quad (3)$$

Given the three possible cases, the manager's objective is to maximize the expected value of the firm in period $t + 1$. Defining investment as $I_t = W_{t-1} - C_t$, the manager's problem can be written as

$$\max_{C_t} (E(W_{t+1})) = \max_{C_t} (p_1 W_{t+1,1} + p_2 W_{t+1,2} + p_3 W_{t+1,3}) = \max_{C_t} \left(\frac{1}{2} \left((W_{t-1} - C_t) E[R]_{t+1} + C_t + H_t \left(1 - \frac{\sqrt{2}}{2} \right) \right) \right. \quad (4)$$

$$+ \frac{1}{2} \frac{C_t(2H_t - C_t)}{H_t^2} \left((W_{t-1} - C_t) E[R]_{t+1} + C_t \frac{\sqrt{2}}{2} \right)$$

$$+ \left. \frac{(H_t - C_t)^2 s_t}{2H_t^2} \left((W_{t-1} - C_t) E[R]_{t+1} - (1 + X_t)(H_t - C_t) \left(\frac{1 - \sqrt{2}}{2} \right) \right) \right).$$

where C_t is the only choice variable. Hence, maximizing Eq. (4) with respect to C_t , the optimal level of cash can be expressed as^{12,13}

$$C_t = \frac{1}{3} \frac{2.83H_t - 2.00(1 - s_t)(W_{t-1} + 2H_t)E[R]_{t+1} - 1.76s_t H_t(X_t + 1) + \sqrt{D}}{1.41 - 2.0E[R]_{t+1}(1 - s_t) - 0.59s_t(X_t + 1)}. \quad (5)$$

Note that Eq. (5) is non-linear. Hence, to test if the model will receive support from the data, we linearize it around the steady state equilibrium:

$$\hat{C}_t = \alpha_1 \hat{W}_{t-1} + \alpha_2 \hat{R}_{t+1} + \alpha_3 \hat{H}_t + \alpha_4 \hat{X}_t + \alpha_5 \hat{s}_t \quad (6)$$

where the coefficients $\alpha_1 - \alpha_5$ are functions of the model's parameters. The expected signs of the coefficients are discussed in the following subsection.

2.2. Model solution

The analytical solution for the firm's optimal cash holdings is a non-linear function of initial resources, W_{t-1} ; the expected gross return on investment, $E[R]_{t+1}$; the gross interest rate for borrowing, X_t ; the bounds of the triangular distribution of cash shocks, H_t and s_t , the probability of acquiring sufficient credit when bankruptcy threatens. Hence the implicit solution is a complicated function of the model's parameters, for which we cannot obtain comparative static results. To address this problem, we resort to graphical analysis to determine the signs of α , the parameters in Eq. (6).

¹¹ We ignore the liquidation value of the firm's real assets, which can be assumed seized by creditors.

¹² Given its quadratic structure, there are two possible solutions to the optimization problem. We work with the solution that implies non-negative cash holdings, as the other solution has no economic meaning.

¹³ D is a function $f(E[R]_{t+1}, X_t, s_t, H_t, W_{t-1})$: $D = 33.17s_t H_t^2 E[R]_{t+1} - 6s_t X_t H_t^2 + 5.66W_{t-1} H_t E[R]_{t+1} + 8s_t(2 - s_t)W_{t-1} H_t E[R]_{t+1}^2 + (7.03s_t X_t + 28)H_t^2 E[R]_{t+1} + (16.49 - 6s_t)H_t^2 + 28E[R]_{t+1}^2 H_t^2 + 4E[R]_{t+1}^2 W_{t-1}^2 - 43.11E[R]_{t+1} H_t^2 + 4s_t^2 E[R]_{t+1}^2 W_{t-1}^2 - 8s_t E[R]_{t+1}^2 W_{t-1}^2 + 4s_t E[R]_{t+1}^2 H_t^2 - 32s_t E[R]_{t+1} H_t^2 - 8E[R]_{t+1}^2 H_t^2 - 5.66s_t E[R]_{t+1} W_{t-1} H_t$.

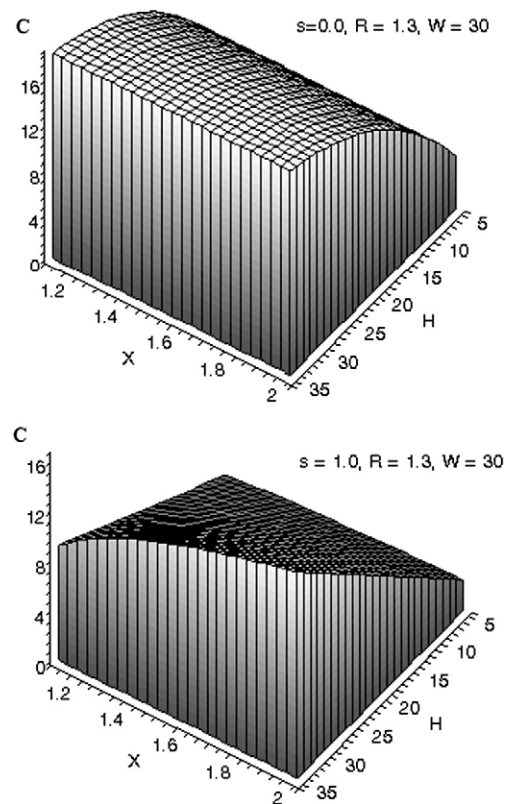

Fig. 1. Plot of C_t against X_t and H_t ($s_t=0$ and $s_t=1$, $W_{t-1}=30$, $E[R]_{t+1}=1.3$).

Fig. 1 presents the relationship among optimal cash holdings, the gross interest rate for external borrowing and the bounds of the cash-flow shock distribution which captures the degree of uncertainty faced by the firm. The figure is plotted setting initial resources $W_{t-1}=30$ and gross returns $E[R]_{t+1}=1.3$ for two different probabilities of raising external funds: $s_t=0$ and $s_t=1$. In the first panel ($s_t=0$), when the firm is subjected to a relatively large negative shock it declares bankruptcy with certainty. When $s_t=1$ the firm receives external financing with probability one, as depicted in the second panel. If no external financing is available ($s_t=0$), cash holdings are high and insensitive to the gross interest rate (X_t): X_t is irrelevant to the firm. The firm always holds more cash regardless of the cost of external financing to guard against the need for external funds. However, if the firm can always acquire external financing, cash holdings are sensitive to the cost of funds. In this case, the firm prefers to hold less cash when funds can be acquired cheaply in comparison to the case where it is more expensive. We also note that the level of cash holdings increases as the bounds of the distribution of cash shocks H_t increases, raising the magnitude of expected cash-flow shocks.

In Fig. 2, we depict the impact of expected returns and changes in the bounds of the cash-flow shock on the cash-holding behavior of the firm. The figure is drawn setting the gross interest rate for external borrowing, $X_t=1.3$ and initial resources $W_{t-1}=30$ while allowing the probability of raising funds to take the values $s_t=0$ and $s_t=0.5$. In this case the optimal level of cash holdings decreases as the expected return on investment $E[R]_{t+1}$ — the opportunity cost of holding liquid assets — increases. An increase in expected returns induces the manager to channel funds towards profitable investment opportunities, *ceteris paribus*. Furthermore, cash holdings are more sensitive to changes in expected returns when $s_t=0.5$ compared to $s_t=0$. However, the impact of a change in the bounds of the cash-flow shock distribution is more complicated. When expected returns are low cash holdings increase as the bounds of the cash-flow shock distribution widen. However, when expected return on investment is much higher optimal cash holdings first increase in response to an increase of the bounds of the cash-flow shock distribution and then decrease. Thus, cash holdings exhibit a complex non-linear relationship to uncertainty in the face of changes in expected returns.

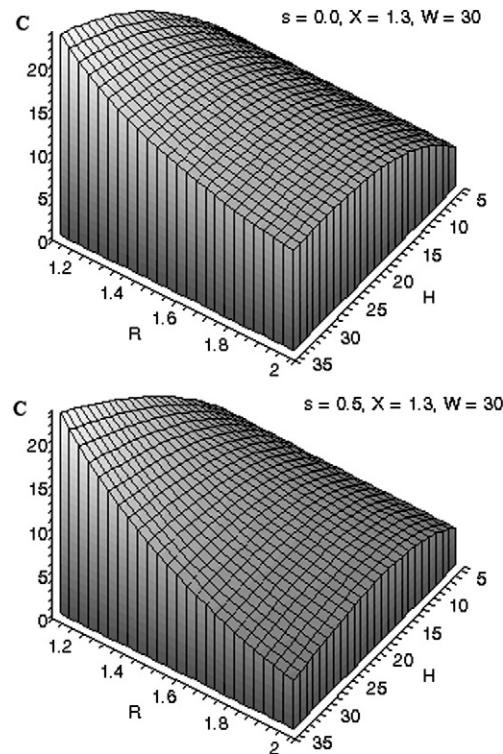

Fig. 2. Plot of C_t against $E[R]_{t+1}$ and H_t ($s_t=0$ and $s_t=0.5$, $W_{t-1}=30$, $X_t=1.3$).

In Fig. 3, we present the relationship among cash holdings, C_t , the bounds of the cash-flow shock distribution H_t and the probability of acquiring sufficient credit when threatened with bankruptcy, s_t . We plot the figure setting initial resources $W_{t-1}=30$ and the gross returns to $R_{t+1}=1.3$ while the gross interest rate for external loans is set to $X_t=1.3$ or $X_t=1.6$. Notice that cash holdings decrease in response to an increase in the probability of getting a loan (a higher s_t). With better odds of external financing, firms are likely to hold less cash, *ceteris paribus*. However, when the costs of external financing are high, cash holdings are less sensitive to the probability of acquiring external financing.

Finally, Fig. 4 describes the relationship among cash holdings, initial resources and the bounds of the cash-flow shock distribution. This figure is constructed setting the gross return $E[R]_{t+1}=1.3$ and the gross interest rate on external borrowing to $X_t=1.3$ while we allow the probability of accessing external funds s_t to equal 0 or 0.5 as in the earlier cases. Here we observe that a firm with higher initial resources will hold more cash. Moreover, as the bounds of the distribution of cash-flow shocks widen, the firm tends to increase its cash holdings due to the precautionary motive.

Given our interpretations of the graphical analysis, our theoretical model predicts positive signs for α_1 (initial resources) and α_4 (interest rate on external borrowing) and negative signs for α_2 (return on investment) and α_5 (probability of being granted sufficient credit). The sign of α_3 (bounds of the cash-flow shock distribution) depends on the levels of the firm's variables.

2.3. Parameterization

In order to find out whether or not the data will support the theoretical model, we must parameterize the coefficients associated with the variables in our model. First consider the firm's expected returns. We assume that the firm maximizes profit, defined as

$$\Pi(K_t, L_t) = P(Y_t)Y_t - w_t L_t - f_t$$

where $P(Y_t)$ is an inverse demand function, f_t represents fixed costs, L_t is labor and w_t is wages. The firm produces output Y given by the production function $F(K_t, L_t)$.

Fig. 3. Plot of C_t against s_t and H_t ($X_t=1.3$ and $X_t=1.6$, $W_{t-1}=30$, $E[R]_{t+1}=1.3$).

Expected return on investment $E[R]_{t+1}$ is equal to the expected marginal profit of capital, which is the contribution of the marginal unit of capital to profit:

$$E[R]_{t+1} = E\left[\frac{\partial \Pi}{\partial K}\right] = \frac{E[P]_{t+1}}{\mu} \frac{\partial Y}{\partial K}$$

where $\mu = 1/(1 + 1/\eta)$ and η is the price elasticity of demand, $\eta = \frac{\partial Y}{\partial P} \frac{P}{Y}$.

Assuming a Cobb–Douglas production function $Y_{t+1} = A_{t+1}K_{t+1}^{\alpha_k}L_{t+1}^{\alpha_l}$ we express the marginal product of capital $\frac{\partial Y}{\partial K}$ as

$$E[R]_{t+1} = \frac{E[P]_{t+1}}{\mu} \frac{\alpha_k Y_{t+1}}{K} = \frac{\alpha_k}{\mu} \frac{E[S]_{t+1}}{K_{t+1}} = \frac{\alpha_k}{\mu} \left(\frac{E[S]_{t+1}}{K_{t+1}} \right) \quad (7)$$

where $E[S]$ denotes expected sales in period $t+1$. We assume rational expectations and replace expected sales at time $t+1$ with actual sales at time $t+1$ plus a firm-specific expectation error term, v_t , which is orthogonal to the information set available at the time when optimal cash holdings are chosen. Moreover, we allow for different profitability of capital across firms and industries, adding an industry specific term, κ , and a firm-specific term, ω . In linearized form we have¹⁴

$$E[\widehat{R}]_{t+1} = \theta \left(\frac{\widehat{S}_{t+1}}{TA_{t+1}} \right) + \kappa + \omega + v_t. \quad (8)$$

¹⁴ We proxy the firm's capital stock K with total assets, TA .

Fig. 4. Plot of C_t against W_{t-1} and H_t ($s_t=0$ and $s_t=0.5$, $E[R]_{t+1}=1.3$, $X_t=1.3$).

The firm's initial resources are $W_{t-1} = C_{t-1} + R_t I_{t-1} + \psi_{t-1}$, where I_{t-1} is investment in period $t-1$, C_{t-1} is cash in the previous period, R_t is the gross return on investment in period t and ψ_{t-1} is the level of the cash-flow shock most recently experienced by the firm. Hence, linearized initial resources are equal to

$$\hat{W}_{t-1} = \zeta_1 \hat{C}_{t-1} + \zeta_2 \hat{I}_{t-1} + \zeta_3 \hat{\psi}_{t-1}. \quad (9)$$

The interest rate on borrowing in the case when the firm does not have enough cash to cover a negative cash-flow shock is taken to be proportional to the risk-free interest rate, TB_t :

$$\hat{X}_t = \delta TB_t. \quad (10)$$

We employ macroeconomic uncertainty and idiosyncratic uncertainty as determinants of the bounds of the distribution of cash-flow shocks:

$$H_t = \beta_1^2 \tau_t^2 + \beta_2^2 \epsilon_t^2 + \beta_1 \beta_2 \text{cov}(\tau_t, \epsilon_t) \quad (11)$$

where τ_t^2 denotes a proxy for the degree of macroeconomic uncertainty while ϵ_t^2 is a measure of idiosyncratic uncertainty. Normalizing the covariance term (a second-order magnitude) to zero, the expression takes the form

$$\hat{H}_t = \beta_1^2 \hat{\tau}_t^2 + \beta_2^2 \hat{\epsilon}_t^2. \quad (12)$$

Finally, the probability of being able to acquire sufficient credit when threatened with bankruptcy, s_t , is parameterized as

$$\hat{s}_t = \gamma_1 \text{LI}_t + \gamma_2 E[\hat{R}]_{t+1} \quad (13)$$

where LI_t is the index of leading indicators: a measure of overall economic health. $E[R]_{t+1}$ is the firm's expected return on investment. Both a stronger economic environment and a higher expected return on investment increase the firm's probability of acquiring sufficient credit if threatened with bankruptcy (see Altman (1968), Liu (2004)).

Substituting the parameterized expressions into Eq. (6) yields

$$\hat{C} = \alpha_1 \zeta_1 \hat{C}_{t-1} + \alpha_1 \zeta_2 \hat{I}_{t-1} + \zeta_3 \hat{\psi}_{t-1} + (\alpha_2 + \alpha_5 \gamma_2) \theta \left(\frac{\hat{S}}{TA} \right)_{t+1} + \alpha_3 \beta_1^2 \hat{\tau}_t^2 + \alpha_3 \beta_2^2 \hat{\epsilon}_t^2 + \alpha_4 \delta TB_t + \alpha_5 \gamma_1 LI_t + (\alpha_2 + \alpha_5 \gamma_2)(\kappa + \omega + \nu).$$

After normalization of cash holdings, debt and investment by total assets we derive our econometric model specification for firm i at time t :

$$\left(\frac{\hat{C}_{it}}{TA_{it}} \right) = \phi_0 + \phi_1 \left(\frac{\hat{C}_{it-1}}{TA_{it-1}} \right) + \phi_2 \left(\frac{\hat{I}_{it-1}}{TA_{it-1}} \right) + \phi_3 \left(\frac{\hat{S}_{it+1}}{TA_{it+1}} \right) + \phi_4 LI_{t-1} + \phi_5 TB_{t-1} + \phi_6 \hat{\psi}_{t-1} + \phi_7 \hat{\epsilon}_{it}^2 + \phi_8 \hat{\tau}_{t-1}^2 + \kappa' + \omega' + \nu' \quad (14)$$

where $\phi_0 - \phi_8$ are complicated functions of the model's parameters and $\epsilon_{it}^2, \tau_{it-1}^2$ represent idiosyncratic and macroeconomic uncertainty, respectively. COMPUSTAT provides end-of-period values for firms, so that we use lagged proxies for macroeconomic variables in the regressions instead of contemporaneous proxies to be consistent with respect to the timing of events. Our first hypothesis — that macroeconomic uncertainty affects firms' cash holdings behavior — can be tested by investigating the significance of ϕ_8 in Eq. (14):

$$\begin{aligned} H_0 &: \phi_8 = 0 \\ H_1 &: \phi_8 \neq 0. \end{aligned} \quad (15)$$

The second hypothesis relates to the role of idiosyncratic uncertainty on the optimal level of cash holdings. This hypothesis can be tested by investigating the significance of ϕ_7 in Eq. (14):

$$\begin{aligned} H_0 &: \phi_7 = 0 \\ H_1 &: \phi_7 \neq 0. \end{aligned} \quad (16)$$

We expect that firms' managers will find it optimal to change their level of liquid asset holdings in response to variations of uncertainty about the macroeconomic environment. Hence, we should be able to reject $H_0: \phi_8 = 0$. Similarly, if an increase in idiosyncratic uncertainty causes an increase in cash holdings, the second hypothesis may be rejected as well.

2.4. Identification of macroeconomic uncertainty

The literature suggests various methods to obtain a proxy for macroeconomic uncertainty. In our investigation, as in Driver et al. (2005) and Byrne and Davis (2002), we use a GARCH model to proxy for macroeconomic uncertainty. We believe that this approach is more appropriate compared to alternatives such as proxies obtained from moving standard deviations of the macroeconomic series (e.g., Ghosal and Loungani (2000)) or survey-based measures based on the dispersion of forecasts (e.g., Graham and Harvey (2001), Schmukler, Mehrez and Kaufmann (1999)). While the former approach suffers from substantial serial correlation problems in the constructed series the latter potentially contains sizable measurement errors.

In an environment of sticky wages and prices, unanticipated *volatility* of inflation will impose real costs on firms and their workers. In this context, we consider a volatility measure derived from changes in the consumer price index (CPI) as a proxy for the macrolevel uncertainty that firms face in their financial and production decisions. To evaluate the robustness of our findings, a second proxy is employed: the volatility of the index of leading indicators. We build a generalized ARCH (GARCH(1,1)) model for each series where the mean equation is an autoregression, as described in Table 1. We find significant ARCH and GARCH coefficients for both time series. The conditional variances derived from this GARCH model are averaged to the quarterly frequency and then employed in the analysis as alternative measures of macroeconomic uncertainty, $\hat{\tau}_t^2$. Table 2 reports the correlation between these series to be relatively low (0.2054). It appears that they reflect different aspects of the macroeconomic environment.

Table 1
GARCH proxy for macroeconomic uncertainty

| | Leading indicators | CPI inflation |

Note: OPG standard errors in parentheses. Models are fit to monthly CPI inflation and the detrended index of leading indicators. ***Significant at 1%.

2.5. Identification of idiosyncratic uncertainty

One can employ different proxies to capture firm-specific risk. For instance, [Bo and Lensink \(2005\)](#) use three measures: stock price volatility, estimated as the difference between the highest and the lowest stock price normalized by the lowest price; volatility of sales measured by the coefficient of variation of sales over a seven-year window; and the volatility of number of employees estimated similarly to volatility of sales. [Bo \(2002\)](#) employs a slightly different approach, setting up the forecasting AR(1) equation for the underlying uncertainty variable driven by sales and interest rates. The unpredictable part of the fluctuations, the estimated residuals, are obtained from that equation and their three-year moving average standard deviation is computed. [Kalckreuth \(2000\)](#) uses cost and sales uncertainty measures, regressing operating costs on sales. The three-month aggregated orthogonal residuals from that regression are used as uncertainty measures.

In contrast to the studies cited above, we proxy the idiosyncratic uncertainty by computing the standard deviation of the closing price for the firm's shares over the last nine months. This measure is calculated using COMPUSTAT items DATA12, 1st month of quarter close price; DATA13, 2nd month of quarter close price; DATA14, 3rd month of quarter close price and their first and second lags. To check the robustness of our results with respect to a proxy for idiosyncratic uncertainty, we estimated a second proxy based on the standard deviation of the sales-to-assets ratio over a seven-quarter window. As [Table 2](#) shows, these two proxies (ϵ_t^2) for idiosyncratic uncertainty are essentially uncorrelated.

To ascertain that the measure captured by this method is different from that used to proxy macroeconomic uncertainty described in Section 2.4, we compute the correlations between the two sets of measures. As [Table 2](#) illustrates, none of the correlations between the τ_t^2 and ϵ_t^2 measures exceed 0.02 in absolute value. Therefore, the macroeconomic and idiosyncratic measures uncertainty are virtually orthogonal.

Table 2
Correlations of uncertainty proxy measures

| | $\tau_{CPI,t}^2$ | $\tau_{LEAD,t}^2$ | $\epsilon_{STOCK,t}^2$ | $\epsilon_{SALE,t}^2$ |
|------------------------|------------------|-------------------|------------------------|-----------------------|
| $\tau_{CPI,t}^2$ | 1.0000 | | | |
| $\tau_{LEAD,t}^2$ | 0.2054 | 1.0000 | | |
| $\epsilon_{STOCK,t}^2$ | 0.0020 | −0.0881 | 1.0000 | |
| $\epsilon_{SALE,t}^2$ | −0.0234 | −0.0117 | −0.0469 | 1.0000 |

3. Empirical implementation

3.1. Data construction

For the empirical investigation we work with Standard & Poor's Quarterly Industrial COMPUSTAT database of U.S. firms. The initial database includes 201,552 firm-quarter characteristics over 1993–2002. We restrict our analysis to manufacturing companies for which COMPUSTAT provides information. The firms are classified by two-digit Standard Industrial Classification (SIC). The main advantage of the dataset is that it contains detailed balance sheet information.

In order to construct firm-specific variables we utilize COMPUSTAT data items Cash and Short-term Investment (DATA1), Depreciation (DATA5), Total Assets (DATA6), Income before Extraordinary Items (DATA8), Capital Expenditures (DATA90 item), Sales (DATA2 item) and Operating Income before Depreciation (DATA21 item). Cash flow is defined as the sum of Depreciation and Income before Extraordinary Items. A measure of cash-flow shocks, ψ , is calculated as the first difference of the ratio of cash flow to total assets.

We apply several sample selection criteria to the original sample. The following observations are coded as missing values in our estimation sample: (a) negative values for cash-to-assets, sales-to-assets and investment-to-assets ratios; and (b) values of investment-to-assets ratio and the idiosyncratic uncertainty measures lower than the first percentile or higher than the 99th percentile. We employ the screened data to reduce the potential impact of outliers upon the parameter estimates. After the screening and including only manufacturing sector firms we obtain on average 700 firms' quarterly characteristics.¹⁵

Descriptive statistics for the quarterly means of cash-to-asset ratios along with investment and sales to asset ratios and ψ are presented in Table 3. From the means of the sample we see that firms hold about 10% of their total assets in cash. This amount is sizable and similar to that reported in Baum et al. (2006).

The empirical literature investigating firms' cash-holding behavior has identified that firm-specific characteristics play an important role.¹⁶ We might expect that a group of firms with similar characteristics (e.g., those firms with high levels of leverage) might behave similarly, and quite differently from those with differing characteristics. Consequently, we split the sample into subsamples of firms to investigate if the model's predictions would receive support in each subsample. We consider four different sample splits in the interest of identifying groups of firms that may have similar characteristics relevant to their choice of liquidity. The splits are based on firm size, durable goods versus non-durable goods producers, markup and firms' growth rate. The durable/non-durable classifications only apply to firms in the manufacturing sector (one-digit SIC 2 or 3). A firm is considered durable if its primary SIC is 24, 25, 32–39.¹⁷ SIC classifications for non-durable industries are 20–23 or 26–31.¹⁸ For the markup split, we compute markup as the ratio of sales to sales net of operating income (before depreciation).

The sample splits for firm size, markup and growth rate are based on firms' average values of the characteristic lying in the first or fourth quartile of the sample.¹⁹ For instance, a firm with average total assets above the 75th percentile of the distribution will be classed as large, while a firm with average total assets below the 25th percentile will be classed as small. As such, the classifications are not mutually exhaustive.

Table 4 gives the number of firm-quarters for each subsample used in our analysis. According to the size category, for example, there are 1508 low-growth large firm-quarters and 2451 high-growth large firm-quarters. Although there is some overlap among the subsample classifications, it is far from complete among the four sets of groupings.

In order to investigate the extent to which cash-to-assets ratios vary among different subsamples we calculate mean comparison tests. The estimated *p*-values for two-sample *t*-tests and Mann–Whitney two-sample statistics²⁰ are

¹⁵ We also use winsorized versions of balance sheet measures and receive similar quantitative results.

¹⁶ See Ozkan and Ozkan (2004).

¹⁷ These industries include lumber and wood products, furniture, stone, clay, and glass products, primary and fabricated metal products, industrial machinery, electronic equipment, transportation equipment, instruments, and miscellaneous manufacturing industries.

¹⁸ These industries include food, tobacco, textiles, apparel, paper products, printing and publishing, chemicals, petroleum and coal products, rubber and plastics, and leather products makers.

¹⁹ We have also experimented with using presample categorization. Our qualitative findings from subsamples are not affected.

²⁰ The Mann–Whitney two-sample test, also known as the Wilcoxon rank-sum test, evaluates the hypothesis that two independent samples are drawn from populations with the same distribution.

| $\epsilon_{\text{STOCK},t}^2$ | 0.0334 | 0.0342 | 0.0120 | 0.0234 | 0.0420 | 30,159 |
| $\epsilon_{\text{SALE},t}^2$ | 0.0404 | 0.0502 | 0.0161 | 0.0276 | 0.0485 | 23,846 |
| $\epsilon_{\text{CPI},t}^2$ | 0.0207 | 0.0083 | 0.0145 | 0.0165 | 0.0291 | 30,885 |
| $\epsilon_{\text{LEAD},t}^2$ | 0.0482 | 0.0084 | 0.0415 | 0.0462 | 0.0519 | 30,885 |

Note: p25, p50 and p75 represent the quartiles of the distribution, N is sample size (number of firm-quarters), while μ and σ^2 represent its mean and variance respectively.

displayed in Table 5. As expected, firms in different subsamples maintain quite different levels of liquidity. On average, small firms hold twice as much cash as do their large counterparts, perhaps reflecting that they have constrained access to external funds. Durable goods makers hold slightly more cash on average than do non-durable goods makers. High-growth (and low-markup) firms hold significantly more cash than low-growth (and high-markup) counterparts, perhaps reflecting their greater cash flow needs. The variations in subsample average liquidity ratios will naturally influence those firms' sensitivity to macroeconomic and idiosyncratic uncertainty.

3.2. Empirical results

Estimates of optimal corporate behavior often suffer from endogeneity problems, and the use of instrumental variables may be considered as a possible solution. We estimate our econometric models using the system dynamic panel data (DPD) estimator. System DPD combines equations in differences of the variables with equations in levels of the variables. In this “system GMM” approach (see Blundell and Bond (1998)), lagged levels are used as instruments for differenced equations and lagged differences are used as instruments for level equations. The models are estimated using a first difference transformation to remove the individual firm effect.

The reliability of our econometric methodology depends crucially on the validity of instruments. We check it with Sargan's test of overidentifying restrictions, which is asymptotically distributed as χ^2 in the number of restrictions. The consistency of estimates also depends on the serial correlation in the error terms. We present test statistics for first-order and second-order serial correlation in Tables 6–8, which lay out our results on the links between macroeconomic uncertainty, idiosyncratic uncertainty and the liquidity ratio. For the “all firms” sample, we also present the full set of coefficients corresponding to the α parameters of Eq. (4). In the interest of brevity, we

Table 5
Cash-to-asset subsamples

| | μ | N | t | M–W |
|---------------------------|--------|--------|--------|--------|
| Small size | 0.1967 | 7610 | 0.0000 | 0.0000 |
| Large size | 0.0782 | 7222 | | |
| Non-durable manufacturers | 0.1145 | 13,061 | 0.0026 | 0.0000 |
| Durable manufacturers | 0.1205 | 17,824 | | |
| Low markup | 0.1999 | 7426 | 0.0000 | 0.0000 |
| High markup | 0.1366 | 8934 | | |
| Low growth | 0.1368 | 6818 | 0.0000 | 0.0000 |
| High growth | 0.1633 | 7524 | | |

Note: the table presents the average cash-to-asset ratios for subsamples and tests for the differences of means. N denotes the number of firm-quarters in each subsample. p -values for the two-sample t -test and Mann–Whitney test are presented as t and M–W, respectively.

only present the coefficients on the uncertainty variables, corresponding to Eqs. (15) and (16) for the subsample splits.²¹

Table 6 displays results for the Blundell–Bond one-step system GMM estimator with the conditional variances of CPI inflation and the index of leading indicators as proxies for macroeconomic uncertainty. Idiosyncratic uncertainty is proxied by the volatilities of closing equity prices or the sales-to-assets ratio. An increase in macroeconomic uncertainty (measured by either proxy) leads to an increase in firms' cash holdings, with a highly significant effect. Idiosyncratic uncertainty is also important, with a significant and positive coefficient estimate. Hence, our findings support the hypotheses that heightened levels of macroeconomic and idiosyncratic uncertainty lead to an increase in the firm's liquidity ratio. The results also suggest significant positive persistence in the liquidity ratio with a coefficient of 0.79. A negative and significant effect of the expected sales-to-assets ratio is also in accordance with our expectations. This ratio may be considered as a proxy for the firm's expected return on investment. When the expected opportunity cost of holding cash increases, firms are likely to decrease their liquidity ratio. Improvements in the state of the macroeconomy (proxied by the index of leading indicators) or increases in the cost of funds (via the Treasury bill rate) will reduce the firm's demand for cash.²² Overall the data for this broadest sample support the basic predictions of the model that we laid out in Section 2.

3.3. Results for subsamples of firms

Having established the presence of a positive role for macroeconomic uncertainty on firms' cash holdings, we next investigate if the strength of the association varies across groups of firms with differing characteristics. It is important to consider that the average cash-to-asset ratios of firms with different characteristics vary widely. The last lines of Tables 7 and 8 present the sample average liquidity ratios ($\mu_{C/TA}$) for each subsample.

The first two columns of Table 7 report results for small and large firms. Based on the point estimates, the former firms are highly sensitive to the changes in volatility of CPI inflation, while large firms display a considerably smaller sensitivity. Small firms also have a much larger coefficient for idiosyncratic uncertainty. The greater sensitivity of small firms could be explained by the fact that smaller firms are more likely to be financially constrained. As Almeida et al. (2004) indicate, financially unconstrained firms have no precautionary motive to hold cash; their cash-holding policies are indeterminate. In contrast, for financially constrained firms, any change in the level of uncertainty that affects managers' ability to predict cash flows should cause them to alter their demand for liquidity. We see that small firms are much more sensitive to both forms of uncertainty, and hold much more cash on average than do large firms.

We find an interesting contrast in the results for durable goods makers and non-durable goods makers, reported in columns 3 and 4. While both categories of firms exhibit positive and significant effects for macroeconomic

²¹ Full results are available on request.

²² Although the analytical model predicts that the Treasury bill rate should be positively related to the liquidity ratio, the model assumes that the firm cannot lend, thus ignoring the opportunity cost of cash holdings.

Sargan is a Sargan–Hansen test of overidentifying restrictions (p -value reported). $AR(k)$ is the test for k -th order autocorrelation. Instruments for System GMM estimations are B/K_{t-3} to B/TA_{t-5} , $CASH/TA_{t-2}$ to $CASH/TA_{t-5}$, I/TA_{t-2} to I/TA_{t-5} , S/TA_{t-2} to S/TA_{t-5} and $\Delta S/TA_{t-1}$, $\Delta CASH/TA_{t-1}$, and $\Delta I/TA_{t-1}$. **Significant at 5%; ***significant at 1%.

uncertainty, durable goods makers also exhibit sensitivity to idiosyncratic uncertainty, which appears to have no significant effect on non-durable goods firms. Durable goods makers' production involves greater time lags and larger inventories of work-in-progress, which may imply a greater need for cash as well as a greater sensitivity to uncertainty.

The first two columns of Table 8 present results for high-markup firms: those in the top quartile of the markup ratio versus their low-markup counterparts. Both categories of firms are sensitive to idiosyncratic uncertainty, with that

sensitivity being almost twice as large for the high-markup firms, who presumably face tighter cash-flow constraints. Macroeconomic uncertainty is also weakly significant for the high-markup firms.

The last two columns report results for high-growth and low-growth firms, respectively. Here again, high-growth firms display sensitivity to idiosyncratic uncertainty, unlike their low-growth counterparts. These firms display significant sensitivity to macroeconomic uncertainty, which may reflect the smaller levels of cash held by those firms.

In summary, we may draw several conclusions from the analysis of these four sets of subsamples. Variations in idiosyncratic uncertainty have a strong effect on the liquidity ratios of small firms, durable goods makers, firms experiencing high growth and firms with high or low markup. Variations in macroeconomic uncertainty have significant effects on liquidity of large, low-growth firms, non-durable goods makers and firms with high markup ratios. The subsample evidence buttresses our findings from the “all firms” full sample and further strengthens support for the hypotheses generated by our analytical model.

4. Conclusions

We set out in this paper to shed light on the link between the level of liquidity of manufacturing firms and uncertainty measures. Based on the theoretical predictions obtained from a simple optimization problem, we first show that firms will increase their level of cash holdings when macroeconomic or idiosyncratic uncertainty increases. This result confirms the existence of a *precautionary motive* for holding liquid assets among non-financial firms. Next we empirically investigate if our model receives support from a large firm-level dataset of U.S. non-financial firms from Quarterly COMPUSTAT over the 1993–2002 period using the dynamic panel data methodology. The results suggest positive and significant effects of both macroeconomic and idiosyncratic uncertainty on firms’ cash-holding behavior, supporting the hypotheses posed in the paper. We find that firms unambiguously increase their liquidity ratio in more uncertain times. The strength of their response differs meaningfully across subsamples of firms with similar characteristics. When the macroeconomic environment is less predictable, or when idiosyncratic risk is higher, companies become more cautious and increase their liquidity ratio.

Our results should be considered in conjunction with those of Baum et al. (2006) who predict that during periods of higher uncertainty firms behave more similarly in terms of their cash-to-asset ratios. Taken together, these studies allow us to conjecture that as either macroeconomic or idiosyncratic uncertainty increases the total amount of cash held by non-financial firms will increase significantly, with negative effects on the economy. The idea behind this proposition is that cash hoarded but not applied to potential investment projects can keep the economy lingering in a recessionary phase. During recessionary periods firms generally are more sensitive to asymmetric information problems; cash hoarding will exacerbate these problems and delay an economic recovery.

Appendix A. Construction of macroeconomic and firm-specific measures

The following variables are used in the empirical study.

From the Quarterly Industrial COMPUSTAT database:

DATA1 Cash and Short-Term Investments
 DATA2 Sales
 DATA5 Depreciation
 DATA6 Total Assets
 DATA8 Income before extraordinary items
 DATA12 1st month of quarter close price
 DATA13 2nd month of quarter close price
 DATA14 3rd month of quarter close price
 DATA21 Operating income before depreciation
 DATA90 Capital Expenditures

From International Financial Statistics:

64IZF Industrial production monthly

From the DRI–McGraw Hill Basic Economics database:

DLEAD index of leading indicators
 FYGM3 three-month U.S. Treasury bill interest rate
